Abstract
Introduction: Vascular endothelial growth factor (VEGF) plays an essential role in development of diabetic macular edema (DME). While there is evidence suggesting that silymarin, a flavonoid extracted from Silybum marianum, could be useful for prevention and treatment of diabetic nephropathy, no studies have been conducted in diabetic retinopathy (DR). The aim of this study was to assess the effect of silymarin on disruption of inner blood retinal barrier (BRB), the primary cause of DME.

Materials and methods: Human retinal endothelial cells (HRECs) were cultured under standard (5.5 mM D-glucose) and diabetogenic conditions (25 mM D-glucose and 25 mM D-glucose + recombinant vascular endothelial growth factor [rVEGF, 25 mg/mL]). To assess cell viability, three concentrations of silymarin were tested (2, 4 and 10 μg/mL). The effect of silymarin on HREC disruption was determined using a dextran (70kD) permeability assay.

Results: No differences were found in the viability of HRECs treated with 2 or 4 μg/mL of silymarin as compared to untreated cells, but viability significantly decreased after using 10 μg/mL. The concentration of 4 μg/mL was therefore selected. Silymarin (4 μg/mL) caused a significant decrease in VEGF-induced permeability in both media with 5.5 mM (422±58 vs. 600±72 ng/mL/cm2; p<0.03) and 25 mM of D-glucose (354±28 vs. 567±102 ng/mL/cm2; p<0.04).

Discussion: Our results show that silymarin is effective for preventing hyperpermeability induced by diabetic conditions in HRECs. Further studies are needed to assess whether silymarin could be useful to treat DME.

Introduction

Diabetic retinopathy (DR) remains the leading cause for vision loss in developed countries. DR is the most frequent microvascular complication, the prevalence of which increases with the duration of diabetes, with an overall rate of up to 30% and a high risk of severe visual impairment in 10% of subjects. Diabetic macular edema (DME) is more frequent in type 2 diabetes, occurs in approximately 7.5% of diabetic patients, and is the main cause of vision loss in working-age adults in industrialized countries.

Vascular endothelial growth factor (VEGF) is a well-known pathogenic factor for the disruption of the blood retinal-barrier (BRB) and together with proinflammatory cytokines play a key role in the development of DME. For this reason, the intravitreal injection of anti-VEGF agents such as ranibizumab, bevacizumab and aflibercept represents the first-line therapy for DME involving the central macula.

Silymarin is a flavonoid extracted from Silybum marianum (Milk thistle), which contains seven major components: taxifolin, silychristin, silydianin, silybin A, silybin B, isosilybin A and isosilybin B. Silymarin has mainly been used to treat liver diseases due to its anti-oxidant, anti-fibrotic, and anti-inflammatory properties. In addition, recent experimental evidence suggests that silymarin has additional effects, which could be useful for prevention and treatment of diabetic complications. In this regard, silymarin is associated with an anti-glycation effect, inhibits aldose reductase, reduces liperperoxidation, and is a partial agonist of peroxisome proliferator-activated receptor γ (PPARγ). Notably, silymarin reduces urinary excretion of albumin, TNF-α, and malondialdehyde (MDA) in patients with diabetic nephropathy.

Lin et al. reported that silybin, a main component of silymarin inhibited VEGF secretion induced by hypoxia in retinal pigment epithelial (RPE) cells, and prevented VEGF- and VEGF plus hypoxia-induced retinal edema. In addition, they also provide evidence that silybin prevented neovascularization in a rat model of age-related macular degeneration (AMD). Zhang et al. reported that silybin treatment significantly prevented the development of obliterated retinal capillaries in diabetic rats. All these findings point to silymarin as a potential therapeutic approach for VEGF induced hyperpermeability condition such as DR. However, the effect of silymarin on the vascular leakage induced by diabetes has not been previously reported.

On this basis, the main aim of the present study is to evaluate the effect of silymarin on VEGF induced hyperpermeability in human retinal endothelial cells (HREC) under standard and high glucose conditions.

Material and methods

Cell cultures

Human retinal endothelial cells (HRECs) were obtained from a vial of cryopreserved cells purchased from Innoprot.
Sylimarin and diabetic retinopathy

To detect changes in the permeability, 100/L9262 (4 ug/mL) with or without rVEGF165 (25 ng/mL) (Figure 1). Measurement conditions included: 5, 5, or 25 mM D-glucose, Silymarin with 100/L600 with the treatments. The lower chamber was filled with cell culture media was changed to medium supplemented with 1% FBS for 24 h and then exposed to different treatments. Recombinant human Vascular Endothelial growth factor (rVEGF165) was purchased from R&D systems (Vitro, Madrid, Spain). Silymarin was purchased from Sigma-Aldrich (Madrid, Spain). 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) were obtained from Sigma-(Madrid, Spain). Cells at passages 2-3 were used for the experiments. For experimentation, HRECs were grown to confluence and then cell culture media was changed to medium supplemented with 1% FBS at 5°C. The medium was removed and the formazan granules obtained were dissolved in 100% dimethyl sulfoxide (DMSO) and absorbance was detected at 562 nm with an ELISA plate reader (ELx800, Bio-Tek Instruments, VT, USA). This assay permitted us to rule out a potential bias in the results due to changes in cell proliferation among the different conditions.

**Cell viability and proliferation**

Cell counting and MTT assay were performed in HRECs to assess the viability of cells treated with silymarin in order to select the appropriate concentration of silymarin. Briefly, HRECs, 1.5 × 10^5 cells/well were seeded into a 96-well plate. Cells were cultured until confluence (48 h) and then arrested by serum deprivation (1%) for 24 h. Then, cells were treated with Silymarin (2, 4 and 10 ug/mL) or rVEGF165 (25 ng/mL) for 48 hours. Cells were stained with DAPI and photographs were taken (20x) in a fluorescent inverted microscope (Olympus IX71 with V-RFL-T Olympus). Cell nuclei were count with the help of Image J software in three different fields for each condition. The experiments were repeated three times. In addition, the MTT assay (Sigma, Madrid, Spain) was used in order to evaluate the viability of cells. Briefly, 10/ul of 5 mg/ml MTT in PBS was added to each well after the treatments and incubated an additional 1 h at 37°C. The medium was removed and the formazan granules obtained were dissolved in 100% dimethyl sulfoxide (DMSO) and absorbance was detected at 562 nm with an ELISA plate reader (ELx800, Bio-Tek Instruments, VT, USA). This assay permitted us to rule out a potential bias in the results due to changes in cell proliferation among the different conditions.

**Measurement of HREC permeability**

Permeability in HREC monolayers was obtained on permeable supports at 1,2 × 10^5 cells/well (24 wells, PFC filters, MerkMillipore, Madrid, Spain). Inserts were incubated for 48 hours at 37°C in 5% CO2-air to form the monolayer. At the end, medium was serum depleted 24 h before to proceed with the treatments. The lower chamber was filled with 600 µL of complete EB medium and the upper chamber with 100 µL of cell suspension in serum depleted (1%). Treatment conditions included: 5, 5 or 25 mM D-glucose, Silymarin (4 ug/mL) with or without rVEGF165 (25 ng/mL) (Figure 1). To detect changes in the permeability, 100 µg/ml of fluorescent FITC-DEXTRAN (70 KDa) (Sigma, Madrid, Spain), was added to the upper side of the insert. Aliquots of 200 µL from the basal compartment were read in a SpectraMax Gemini (Molecular Devices, Sunnyvale, CA) at a wavelength of excitation/emission 485/528 nm every 30 min. Finally, the concentration of dextran was determined by extrapolation of the fluorescence reads in a standard curve. Each condition was tested in triplicate.

**Statistics**

Data are presented as means ± SD. Comparisons of continuous variables were performed using ANOVA and Student’s t test with SPSS software (SPSS Inc. Released 2009. PASW Statistics for Windows, Version 18.0 Chicago: SPSS Inc.). The statistical significance level was set at p <0.05.

**Results**

No significant differences were found in the viability in HREC treated with 2 or 4 µg/mL of silymarin in comparison with untreated cells (Figure 2). By contrast, in HREC treated with 10 µg/mL of silymarin a significant reduction of viability was observed. Silymarin at the high concentration tested decreases cell viability, and therefore to evaluate its effect on BRB permeability the concentration of 4 µg/mL was used.

Permeability of HREC monolayers were higher in high glucose (25 mM) conditions in comparison with normal glucose conditions (5.5 mM) (403 ± 140 vs. 206 ± 26; p <0.008) (Figure 3). rVEGF165 (25 ng/mL) significantly increased the permeability of 70 kDa-Dextran through HRECs monolayers cultured under both, normal (600 ± 72 vs. 206 ± 47 ng/mL/cm2; p <0.02) and high glucose conditions (567 ± 102 vs. 403 ± 64 ng/mL/cm2; p <0.05). Silymarin (4 µg/mL) produced a significant decrease of VEGF induced permeability under either 5.5 mM (422 ± 58 vs. 600 ± 72 ng/mL/cm2; p <0.03) or 25 mM of D-Glucose (354 ± 28 vs. 567 ± 102 ng/mL/cm2; p <0.04) (Figure 3).

**Discussion**

Vascular leakage due to the breakdown of the BRB is the main event involved in the pathogenesis of DME. In the present study, we demonstrated that silymarin significantly prevented the VEGF-induced vascular hyperpermeability in HREC, which constitutes the inner BRB. It should be noted that the concentration of silymarin used was in the same range or even lower than reported in previous in vitro studies. In recent years three classes of drugs (renin-angiotensin [RAS] system blockers, fenofibrate and calcium dobesilate monohydrate [CaD]) have emerged as potential systemic treatments for DR. The anti-inflammatory and/or the antioxidant actions of these drugs have been reported among the underlying mechanism involved in their beneficial effects on DR. However, the current clinical evidence does not support the concept that RAS blockers possess an extra value in preventing or arresting the progression of DR in

hypertensive patients when compared with other anti-hypertensive agents.26

Several sub-studies have demonstrated that fenofibrate (a PPARα agonist used as a hypolypidemic agent) has been useful in arresting the progression of DR but not in preventing its development and, therefore, it seems reasonable to propose its use for patients with preexisting DR.27 However, fenofibrate for DR treatment has been approved only in Australia, Singapore, Philippines and Malaysia, and a specific clinical trial aimed at determining its efficiency in preventing DR worsening is needed. Finally, CaD has been approved for the treatment of DR for many years in several countries but it has not been widely used for this purpose in clinical practice. A poor understanding of its mechanisms of action has been one of the reasons for this. However, recent experimental evidence unraveling multifaceted mechanism of action at retinal level seems to support clinical trials showing beneficial effects in early stages of DR.28

Silymarin is extracted from the plant Silybum marianum which is one of the most commonly plants used in liver diseases treatments. Silymarine is considered hepatoprotective and it has been widely used in patients with cirrhosis, chronic hepatitis and liver disease associated with alcohol consumption and exposure to environmental toxins.29 Currently, it is one of the most studied medicinal herbs for the treatment of non-alcoholic fatty liver disease (NAFLD) and steatohepatitis (NASH) and its use has been shown to be safe and well tolerated even for these patient groups. The therapeutic dose of silymarin described in clinical studies ranges between 200-800 mg/day.30

We found that the highest concentration of silymarin evaluated in this study (10 µg/ml) reduces HREC viability. In this regard, experimental evidence suggest that silymarin could be useful for cancer treatment in view of their pro-apoptotic effect, primarily p53 dependent, as well for its anti-angiogenic effects.23-25 It must be noted that these effects were observed in vitro in cultures of tumoral cells (colon, prostate, breast and skin cancer) using a concentration equal or higher than 40 µg/ml. However, our results suggests that in HREC the threshold concentration to promote apoptosis is lower than in tumoral cells.

To the best of our knowledge, there are no studies on the anti-permeability effect of silymarin in endothelial cells. However, it has been reported that silymarin decreases the microalbuminuria in diabetic patients,18 which is closely related to endothelium impairment. We have found a strong inhibitory effect of silymarin on VEGF induced permeability, which is one of the most important pathogenic events in the development of DME. In addition, the antiangiogenic properties demonstrated in oncologic experimental studies point to silymarin as a potential candidate for treatment of proliferative diabetic retinopathy. Overall, these findings open

Conflict of interest

In conclusion, our results provided evidence that silymarin is effective to prevent BRB disruption, thus reducing vascular leakage. However, further studies to evaluate whether silymarin treatment could be useful for DME are needed.
